ABSTRACT

To determine the genetic variability of dengue viruses (DENVs) in Paraguay, the complete envelope gene was sequenced for 4 DENV-2 and 22 DENV-3 strains isolated from 2001 to 2006. The sequence data were used in Bayesian phylogenetic analyses, which revealed that Paraguayan DENV-2 strains fell into two distinct clades within the American/Asian genotype, thus suggesting that the introduction of a new DENV-2 clade was likely associated with the shift of dominant serotype from DENV-3 to DENV-2 in 2005 and might have caused an outbreak of DENV-2. This study also indicated that DENV-3 strains fell into genotype III, of which, several 2006 isolates varied from the remaining isolates in their tree locations. The introduction of this new clade was likely associated with the shift of dominant serotype from DENV-2 to DENV-3 in 2006 and might have caused an epidemic of DENV-3. More data are needed to test this hypothesis.

Dengue viruses (DENVs) belong to the family *Flaviviridae*, genus *Flavivirus*, and species *Dengue virus*. They are transmitted by mosquitoes, principally *Aedes aegypti*, and distributed in tropical and subtropical regions all over the world, predominantly in urban and semi-urban areas. They exist as four serotypes (DENV-1, -2, -3, and -4). Infections by any of the four serotypes can result in either subclinical manifestations or a mild, self-limiting disease, dengue fever (DF), or a severe disease, dengue hemorrhagic fever (DHF), which can progress to dengue shock syndrome (DSS) and death. Severe and fatal hemorrhagic disease is more often associated with DENV-2 and -3 infections (Gubler, 1998). Dengue fever has emerged as one of the most important arboviral diseases, with an estimated 50–100 million dengue infections occurring annually in more than 100 countries (Gubler, 2006). There are currently neither licensed vaccines nor antiviral drugs available for the DENVs. Little is under-

stood about DENV pathogenesis. The recently developed models could prove the importance of viral genotypes in causing severe epidemics (Rico-Hesse, 2007).

In America, during the 1940s and 1950s, the Pan American Health Organization (PAHO) initiated a mosquito control program. Thanks to the success of this program, *A. aegypti* eradication was achieved in most countries. In the 1970s, due to the collapse of this program, *A. aegypti* reinfested. The expanding distribution of *A. aegypti* coincided with increased movement of DENVs both into and within America (Gubler, 1997). Although dengue was endemic in some regions, it was not a major public health concern in America until 1981, when the first major DHF epidemic occurred in Cuba, with an estimated 10,000 cases of DHF/DSS (Kouri et al., 1989).

In Paraguay, DENV-1 was first detected in 1988, and caused an epidemic of DENV-1 in the year 2000, along with more than 27,000 DF cases (Aviles et al., 2002, 2003). DENV-2 and -3 were isolated for the first time in 2001 and 2002, respectively (Aquino et al., 2006). In 2007, a large outbreak of DENV-3 epidemic occurred. Up to 9 April 2007, a total of 25,021 dengue cases were reported, along with 52 cases of DHF and 13 deaths. The outbreak was concentrated in Asunción (the capital) and five other locations (PAHO, 2007a,b). Until now, only limited data concerning Paraguayan DENV-3 (Aquino et al., 2006) and no data concerning Paraguayan DENV-2 have been available. In order to provide more information on the DENVs'

molecular epidemiology in Paraguay and elucidate the mode of DENV transmission in South America, we conducted this study. This paper reports the results of the nucleotide sequencing of the complete envelope (E) gene of Paraguayan DENV-2 and -3 strains isolated from 2001 to 2006, and their phylogenetic relationships were also analyzed.

A total of 4 DENV-2 and 22 DENV-3 strains were kindly provided, which were originally isolated from patient sera in the Departamento de Investigación del Laboratorio Central de Salud Pública, Ministerio de Salud Pública y Bienestar Social in Asunción, Paraguay. The information on the clinical disease was not provided. These isolates were passaged not more than twice in C6/36 cells in our laboratory, and the resultant viruses were analyzed in this study. Viral RNA was extracted from cell culture supernatant using ISOGEN-LS (Nippon Gene), according to the manufacturer's instructions. RT-PCR was performed using SUPERSRIPT™ One-Step RT-PCR with PLATINUM® Taq (Invitrogen). RT-PCR products were purified with the QIAquick PCR Purification Kit (Qiagen). The purified products were sequenced with the BigDye® Terminator v1.1 Cycle Sequencing Kit (Applied Biosystems), followed by purification using CENTRI-SEP COLUMNS (Princeton Separations). The sequencing reactions were analyzed on a model 310 Genetic Analyzer (Applied Biosystems). Both strands of cDNA were sequenced (Tang et al., 2005). The primers for DENV-2 referred to those published by Anzai et al. (2004). The primers for DENV-3 were modified from those published by Lanciotti et al. (1994), as follows: first pair (P722 and CP1559), second pair (P1262: 5'-AAGGGAAGCTTGGTGACATGCGC-3' and CP1816: 5'-CCCTTTGAGTTTCAATTTGTCAT-3'), and third pair (P1685 and CP2550: 5'-ATGGCTGTGCCACTCTTTTGGGGGA-3').

The viral envelope affects viral packaging, host-cell entry, and immune response. The entire E sequences of 26 Paraguayan DENV strains were determined, and aligned using the Clustal X software package (Thompson et al., 1997). Phylogenies were estimated using Bayesian (MrBayes v3.1.2) analyses. Bayesian phylogenetic trees with posterior probabilities were generated in this study. They were run with a general time reversible substitution model (3 million generations, with a 3000-tree-burn-in). The substitution rates were assumed to follow a gamma plus invariants distribution (Huelsenbeck et al., 2001; Ronquist and Huelsenbeck, 2003). The chain length was determined by use of the Tracer program (Rambaut and Drummond, 2007), giving the effective sample sizes of over 1900 and 1700 for DENV-2 and -3 strains, respectively.

DENV-2 envelope gene is 1485 nucleotides in length and encodes a polypeptide of 495 amino acids. Four DENV-2 strains were sequenced. The E nucleotide sequences of the two 2001 isolates were found to be identical, so only one (D2PY-04/01) of these two isolates was deposited in GenBank (Table 1), and used in the phylogenetic analysis (Fig. 1). The deduced amino acid sequences of D2PY-04/01 and D2PY-21/05 were found to be identical. In comparison to these sequences, D2PY-22/05 possessed four amino acid substitutions at E61 (V to I), E131 (Q to L), E203 (D to E), and E239 (T to N). In addition, two substitutions at E131 and E239 were non-conservative.

It has been proposed that DENV-2 isolates be divided into six genotypes: American/Asian, American, Cosmopolitan, Sylvatic, Asian I, and Asian II (Twiddy et al., 2002). The phylogenetic tree of global DENV-2 strains is presented in Fig. 1(a). In America, the 1981 epidemic of DHF/DSS was attributed to the introduction of a new DENV-2 genotype (Rico-Hesse et al., 1997). Since the early 1980s, the American/Asian genotype, originally from Asia, has established and spread throughout America, replacing the native American genotype. This displacement took place in the Caribbean during the 1980s; in northern South America and Brazil in the early 1990s; in Central America, Bolivia and Peru in the late 1990s; and in Mex-

ico in 2000 (Anzai et al., 2004; Bennett et al., 2006; Diaz et al., 2006; Foster et al., 2004; Regato et al., 2008; Rico-Hesse et al., 1997; Uzcategui et al., 2001).

Paraguayan DENV-2 isolates fell into two distinct clades within the American/Asian genotype (Fig. 1(b)). Two strains (D2PY-04/01 and D2PY-21/05), together with some other strains possessing Q at E131, from the Dominican Republic, Cuba, Venezuela, Mexico, and Nicaragua, formed one clade. While another isolate (D2PY-22/05) fell into a separate clade, along with some other isolates possessing L at E131, from Brazil, Bolivia, Colombia, Peru, and Venezuela. D2PY-22/05 was more closely related to the Brazilian and Bolivian strains. Our results support the notion that the amino acid at E131 is an important genetic marker for phylogenetic classification of DENV-2 (Bennett et al., 2006; Foster et al., 2004). Residue E131 is located within a pH-dependent hinge region at the interface between domains I and II of envelope protein. Mutations at this region may affect the pH threshold of fusion and the process of conformational changes (Modis et al., 2003, 2004). In other flaviviruses, mutations in this hinge may also play important roles (Modis et al., 2003; Tang et al., 2005; Zhao et al., 2005).

To our knowledge, this is the first report on a phylogenetic analysis of DENV-2 in Paraguay. It was noticeable that a new DENV-2 clade was introduced and two distinct clades of viruses co-circulated there in 2005. In Paraguay, 38 dengue cases were reported in 2001, with either DENV-1 or -2 as the etiologic agents (PAHO, 2002). In 2005, an outbreak of DENV-2 occurred and 405 dengue cases were reported (PAHO, 2007a). This outbreak was therefore suggested to possibly have been due to the introduction of a new DENV-2 clade, which was found to be likely associated with the shift of dominant serotype from DENV-3 to DENV-2 in 2005 (PAHO, 2007a). More data are needed to test this hypothesis. It was reported that an increase in DENV-1 clade diversity was associated with an increase in the abundance of this serotype and a concomitant decrease in DENV-4 prevalence in Thailand, and cross-protective immunity could account for it (Adams et al., 2006; Zhang et al., 2005).

DENV-3 envelope gene is 1479 nucleotides in length and encodes a polypeptide of 493 amino acids. Twenty-two DENV-3 strains were sequenced. For purposes of simplicity and clarity of the subsequent phylogenetic analysis, we deposited only one of those isolates showing an identical nucleotide sequence in GenBank, removing the remaining isolates. So, only 12 of the 22 DENV-3 strains were included in Table 1 and Fig. 2. For example, a total of six 2006 isolates were obtained, the E sequences of four strains from Asunción were found to be identical, only one (D3PY-28/06) of them was deposited in GenBank, the other three strains were not shown in this report, this case was notable. A comparison of amino

Fig. 1. (a) Bayesian phylogenetic tree derived from DENV-2 E gene sequences. The tree was rooted with DENV-1 Mochizuki and DENV-4 814669 strains. The numbers near key nodes indicated posterior probabilities of the corresponding clade. All horizontal branch lengths were drawn to scale. The viruses were listed by strain name, country of origin, and the last two digits of the year of isolation. Paraguayan isolates in this study appeared in bold. (b) Bayesian phylogenetic tree of DENV-2 American/Asian genotype shown for purpose of clarity only. Strains 04/China/85 and D89-828/Thailand/89 served as outgroup.

acid sequences of Paraguayan DENV-3 strains revealed that the two most recent isolates (D3PY-26/06 and D3PY-28/06) shared three substitutions at E302 (N to K), E360 (E to D), and E471 (T to I), of which, two substitutions at E302 and E471 were non-conservative. D3PY-26/06 possessed an additional substitution at E405 (R to K). It is notable that the mutation at E302 is located within one (residues 301–307) of the four proposed serotype-specific epitopes of DENV-3 (Modis et al., 2005), its impact on immune recognition requires further study.

It has been proposed that DENV-3 isolates be divided into five genotypes: genotype I, II, III, IV, and V (Wittke et al., 2002). The phylogenetic tree of global DENV-3 strains is presented in Fig. 2(a). It has been reported that the emergence of DHF in Sri Lanka in 1989 was associated with the appearance of a new DENV-3 variant, belonging to genotype III, which then spread into America via Africa (Messer et al., 2003). After an absence of 17 years, DENV-

3 was reintroduced into America in 1994, thus causing a small outbreak of classic DF in Panama and a major DF/DHF epidemic in Nicaragua (CDC, 1995). Subsequently, DENV-3 spread into Central America and Mexico. In 1998/1999, DENV-3 was introduced into Caribbean countries such as Puerto Rico, Jamaica and Martinique; and finally in 2000, into South American countries such as Venezuela and Brazil (Aquino et al., 2006; Diaz et al., 2006; Regato et al., 2008; Rodriguez-Roche et al., 2005; Uzcategui et al., 2003).

Paraguayan DENV-3 isolates fell into genotype III (Fig. 2(b)). The one most recent isolate, D3PY-27/06, and all the older Paraguayan strains (isolated before 2006) clustered into one clade, together with some Brazilian isolates and one Bolivian isolate. The other two most recent strains (D3PY-26/06 and D3PY-28/06) and one Brazilian 2004 isolate grouped outside this clade, forming another clade. It was noticeable that both strains of D3PY-26/06 and D3PY-28/06 were sampled in Asunción, the most severely affected location

Fig. 2. (a) Bayesian phylogenetic tree derived from DENV-3 E gene sequences. The tree was rooted with DENV-1 Mochizuki, DENV-2 NGC, and DENV-4 814669 strains. The numbers near key nodes indicated posterior probabilities of the corresponding clade. All horizontal branch lengths were drawn to scale. The viruses were listed by strain name, country of origin, and the last two digits of the year of isolation. Paraguayan isolates in this study appeared in bold. during the period of the 2006–2007 DENV-3 epidemics. In Paraguay, 137 and 164 dengue cases were respectively reported in 2003 and 2004, with DENV-3 as the etiologic agents. In 2006, an epidemic of DENV-3 occurred and 4271 dengue cases were reported. DHF cases were reported for the first time in 2007 (PAHO, 2007a). Further study is required regarding the association of the introduction of this new clade with the epidemic of DENV-3 and the shift of dominant serotype from DENV-2 to DENV-3 in 2006 (PAHO, 2007a). Only the 2002–2003 data on the molecular epidemiology of DENV-3 in Paraguay are available (Aquino et al., 2006). In this report, we characterized some more recent isolates to fur-

ther understand the ecology of DENV-3 in this country, finding that several 2006 isolates were quite different from the older strains and were likely associated with the shift of dominant serotype. Due to the geographic proximity and socioeconomic ties between countries, Paraguayan DENV-3 strains were closely related to the isolates from Brazil.

The increased surveillance is required to evaluate the risk for increased pathogenic potential of circulating DENV strains. The introduction of new DENV genotypes and serotypes is a major risk factor for epidemic dengue and severe disease. The genomic sequence determination of these viruses is an important step

for achieving a more precise phylogenetic classification in the future.

Acknowledgements

We are grateful to the staff at the Departamento de Investigación del Laboratorio Central de Salud Pública, Ministerio de Salud Pública y Bienestar Social of Paraguay for kindly providing dengue isolates for our study. We would also like to thank Dr. A. Shichijo, a former staff of the Japan International Cooperation Agency, for his assistance in this study.
